CNS SPECTRUMS

CME Review Article

Keeping up with the clinical advances: depression

This activity is provided by the Neuroscience Education Institute.

Additionally provided by the American Society for the Advancement of Pharmacotherapy.

CME Information

Learning Objectives

After completing this activity, you should be better able to:

- Explain the role of glutamate, gamma-butyric acid, and non-monoamines in treating major depression
- Describe the novel glutamate, gamma-butyric acid, and opioid modulating agents currently being investigated for depression

Accreditation and Credit Designation Statements

The Neuroscience Education Institute (NEI) is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians.

NEI designates this enduring material for a maximum of 1.0 *AMA PRA Category 1 Credit*™. Physicians should claim only the credit commensurate with the extent of their participation in the activity. A posttest score of 70% or higher is required to earn CME credits.

The American Society for the Advancement of Pharmacotherapy (ASAP), Division 55 of the American Psychological Association, is approved by the American Psychological Association to sponsor continuing education for psychologists. ASAP maintains responsibility for this program and its content.

The American Society for the Advancement of Pharmacotherapy designates this program for 1.0 CE credit for psychologists.

Nurses and *Physician Assistants:* for all of your CE requirements for recertification, the ANCC and NCCPA will accept *AMA PRA Category 1 Credits*™ from organizations accredited by the ACCME. The content of this activity pertains to pharmacology and is worth 1.0 continuing education hour of pharmacotherapeutics.

Optional Posttest and CME Credit Instructions

1. Read the article
2. Complete the posttest and evaluation, available only online at www.neiglobal.com/CME (under "CNS Spectrums")
3. Print your certificate (passing score = 70% or higher)

Major depressive disorder (MDD) is a prevalent and heterogeneous disorder. Although there are many treatment options for MDD, patients with treatment-resistant depression (TRD) remain prevalent, wherein delayed time to response results in inferior chances of achieving remission. Recently, therapeutics have been developed that depart from the traditional monoamine hypothesis of depression and focus instead on the glutamatergic, GABAergic, opioidergic, and inflammatory systems. The literature suggests that the foregoing systems are implicated in the pathophysiology of MDD and preclinical trials have informed the development of pharmaceuticals using these systems as therapeutic targets. Pharmaceuticals that target the glutamatergic system include ketamine, esketamine, and rapastinel; brexanolone and SAGE-217 target the GABAergic system; minocycline targets the inflammatory system; and the combinatory agent buprenorphine + samidorphan targets the opioidergic system. The aforementioned agents have shown efficacy in treating MDD in clinical trials. Of particular clinical relevance are those agents targeting the glutamatergic and GABAergic systems as they exhibit rapid response relative to conventional antidepressants. Rapid response pharmaceuticals have the potential to transform the treatment of MDD, demonstrating reduction in depressive symptoms within 24 hours, as opposed to weeks noted with conventional antidepressants. Novel therapeutics have the potential to improve both patient mood symptomatology and economical productivity, reducing the debased human capital costs associated with MDD. Furthermore, a selection of therapeutic targets provides diverse treatment options which may be beneficial to the patient considering the heterogeneity of MDD.

Introduction

Major depressive disorder (MDD) has been classified by the World Health Organization as the leading cause of disability and illness worldwide.[1] With a global prevalence of over 300 million people, MDD poses a significant economic burden through its associated medical costs, mortality costs, and workplace costs.[2] The core symptoms of depressed mood and anhedonia do not explicate the extent of disability observed with the disorder. Indeed, there are additional comorbid functional and cognitive dysfunctions that contribute to the debilitating nature of MDD.[3]

Given the complexity of MDD, it has proven difficult to treat, as evident by the rate of treatment-resistant depression (TRD). TRD is characterized as non-response to one or more treatments, with the likelihood of achieving remission decreasing with each subsequent treatment step.[4] TRD is experienced by approximately 12–20% of those with MDD.[5] Of note, those with TRD have reported lower workplace productivity and social functioning, as well as depression rating scores indicative of more severe depression compared to those with non-TRD.[6] Furthermore, the costs associated with TRD are higher compared to those with non-TRD, and it has been suggested that TRD is driving the capital costs associated with depression.[7] Given the prevalence of TRD and its associated functional debilitations, there is interest in developing both effective and fast-acting treatment options. Notably, fast-acting therapeutics may aid in reducing the capital cost associated with depression by decreasing absenteeism and presenteeism, wherein absenteeism and presenteeism have been shown to be major contributors to costs associated with MDD.[8]

Table 1. Summary of novel pharmaceuticals for treatment of MDD

Pharmaceutical name	Sponsor	Clinical trial phase	Regulatory affairs
Glutamatergic system			
Ketamine	Multiple	Phase III/IV	Not approved by FDA for MDD. Widely used off-label.
Esketamine	Janssen Pharmaceutical Companies of Johnson and Johnson	Phase III	Breakthrough therapy designation for MDD and TRD[36]
Rapastinel	Allergan	Phase III	Fast-track designation and breakthrough therapy designation for MDD (2014 and 2016)[39]
AV-101	VistaGen therapeutics, Inc.	Phase II	Fast track designation for adjunctive treatment of MDD (2018)[44]
AGN-241751	Allergan	Phase II	Fast-track designation for treatment of MDD (2018)[46]
AXS-05	Axsome	Phase III	Fast-track designation for treatment of TRD and breakthrough therapy designation for TRD (2019)[42]
GABAergic system			
Brexanolone	Sage therapeutics	Phase III	Sponsor filed a new drug application with the FDA, and the FDA advisory committee voted in favor of the benefit-risk profile. Awaiting approval.[57,58]
SAGE-217	Sage therapeutics	Phase III	Breakthrough therapy designation for MDD (2018)[61]
Inflammatory system			
Minocycline	Various	Phase II	Not approved by FDA for MDD. Clinical trials for use off-label
Opioidergic system			
Buprenorphine + samidorphan	Alkermes plc	Phase III	Fast-track status for adjunctive treatment of MDD (2013);FDA did not approve in current state and is requesting additional evidence of effectiveness (2019)[87]

Note: FDA: US Food and Drug Administration; MDD: major depressive disorder.

First-line treatment for MDD typically includes a selective serotonin reuptake inhibitor (SSRI) or a serotonin-norepinephrine reuptake inhibitor (SNRI).[9] The use of SSRIs and SNRIs in MDD accords with the monoamine hypothesis of depression. The monoamine hypothesis posits that MDD is caused by a deficit in monoamine systems (i.e., serotonin, noradrenaline, or dopamine). While SSRIs and SNRIs have demonstrated efficacy in alleviating mood symptomatology, there remains a high percentage of non-responders. Therapeutic strategies for non-responders include switching or combining antidepressants and augmenting antidepressant therapy with a non-antidepressant agent.[10] Given the number of US Food and Drug Administration (FDA)–approved SSRIs for MDD (e.g., citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, vilazodone), the high prevalence of those with TRD and with non-response to monoamine antidepressants suggests that monoamine dysregulation does not fully account for depressive symptomatology and that other targets should be explored.[11]

During the past one to two decades, several alternative therapeutic targets have been identified, such as the glutamatergic pathway, the gamma-aminobutyric acid (GABA) pathway, the opioidergic pathway, and the inflammatory pathway. Not only do these novel pathways have the potential to offer effective alternative treatment for those with TRD, but benefits have also been observed in non-affective domains such as cognition.[12] In addition, alternative mechanisms of action may change the traditional treatment course by providing rapid symptomatic relief (i.e. hours), when compared to traditional antidepressants (e.g., 4–6 weeks).[13] For example, suicidal ideation is a potential area of improvement with rapid antidepressant response. As it has been suggested that rapid time to response can mediate increased suicidal behavior occasionally observed after starting antidepressant treatment, such that suicidal risks decrease in those with early antidepressant response.[14,15] Improving the time to response could fundamentally change approaches to treatment and offer considerable improvements for patients. The current review covers the antidepressant action of the glutamatergic, GABAergic, opioidergic, inflammatory systems, and those associated novel therapeutics that have demonstrated considerable efficacy in recent clinical trials (Table 1 provides a list of all pharmaceutical agents discussed, sponsors, current trial phases, and regulatory affairs).

Glutamate

Glutamate is the principal and most abundant excitatory neurotransmitter in the brain. A wealth of preclinical and clinical data posit that the glutamatergic system has a role in mood regulation.[16,17] Furthermore, neurological differences in glutamate, glutamine, and their

metabolites have been observed in those with MDD. Those with MDD have lower neural concentrations of the aforementioned than healthy controls and their concentrations can be increased following successful treatment.[17-19] Conversely, high plasma blood glutamate levels have been reported in those with MDD, and following antidepressant treatment with monoamine-based antidepressants, decreases in blood glutamate levels have been reported.[20,21] It follows that monoamine-based antidepressants impact the glutamatergic system and that the glutamatergic system may be involved in MDD.

Regulation of the glutamatergic system to treat mood disorders is typically achieved through interaction with glutamate release or glutamate receptors. Receptors are classified as ionotropic (i.e. forming a ligand gated ion channels) or metabotropic (i.e. activating coupled G-proteins). Various ionotropic receptors have been documented, including *N*-methyl-d-aspartate (NMDA), α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), and kainic acid. Three groups of metabotropic glutamate receptors (mGluRs) have also been identified. Mechanistically, it has been suggested that NMDA antagonists increase the AMPA to NMDA neurotransmission ratio, which has shown to have antidepressant-like effects in preclinical models.[22] Furthermore, AMPA and the brain-derived neurotrophic factor (BDNF) have a bidirectional interaction, wherein increases in AMPA facilitate increases in BDNF expression, which can result in enhanced neuronal plasticity.[23] Notably, dysregulation of this system can produce negative changes in neuronal plasticity associated with MDD.[24]

Novel therapeutics

Ketamine and ketamine-like agents

Ketamine. Ketamine is a high-affinity NMDA receptor antagonist. While not approved by the FDA for the treatment of MDD, ketamine has been increasingly used off-label for psychiatric disorders wherein the most common use was MDD.[25] Ketamine is most often administered via an intravenous infusion over 40 minutes using subanesthetic doses in the range of 0.10–0.75 mg/kg.[26] Metabolism of ketamine occurs in the liver and is achieved primarily by CYP3A4 and in lesser amounts by CYP2B6 and CYP2C9.[27] A meta-analysis exploring the efficacy of ketamine for use with MDD in randomized control trials found that those receiving ketamine had improved response rates versus placebo at 24 hours, 72 hours, and 7 days post-infusion, where response was defined as a minimum of 50% reduction in absolute Hamilton Depression Rating Scale scores (HAM-D), Montgomery–Åsberg Depression Rating Scale (MADRS), or significant improvements in the Clinical Global Impression Scale (CGI). Furthermore, results at all time points were highly significant ($p < 0.00001$).[28] Of clinical relevance is the time to response to ketamine wherein, following a single infusion, antidepressant effects can be observed within 4 hours.[29] Notably, the use of ketamine for MDD has been associated with psychotomimetic effects post-infusion and may have the potential for abuse.[30] Methods by which the aforementioned potential adverse events could be mitigated include dosing modification, co-administration with other agents, alternative routes of administration, and isometric formulations.[31] Esketamine and, in particular, rapastinel have been suggested as alternative formulations that have demonstrated rapid response with fewer (particularly in the case of rapastinel) psychotomimetic side effects.[32,33] In addition to its rapid response, ketamine may have pro-suicidal effects such that ketamine has demonstrated efficacy in rapidly reducing suicidality in patients with TRD.[34] Notably, while the antidepressant action of ketamine is often attributed to its NMDA properties, one study has suggested that opioid receptors are involved in ketamine's antidepressant effects. Indeed, when naltrexone (i.e., an agent that blocks neurological opioid receptors) is administered to ketamine responders' pre-ketamine treatment, the antidepressant effects typically observed with ketamine are significantly attenuated relative to placebo. However, naltrexone pretreatment relative to placebo did not significantly impact ketamine-induced dissociation, suggesting that ketamine's dissociative effects are largely independent of its action on the opioid receptors.[35] Ultimately, further studies are needed to elucidate the mechanism of action of ketamine and explore the role of opioid receptors in relation to ketamine's efficacy.

Esketamine. Esketamine is the *S*-enantiomer of ketamine (i.e. the *R*-enantiomer) and similarly, a NMDA receptor antagonist. Esketamine has been given breakthrough therapy designation from the FDA for both TRD and MDD with imminent risk for suicide.[36] Esketamine is administered intranasally as a nasal spray and, to date, clinical trials have used self-administered doses from 14 to 84 mg over various time points (e.g., twice weekly, weekly, and biweekly).[37] Esketamine is metabolized similarly to ketamine by CYP3A4 and, in lesser amounts, by CYP2B6 and CYP2C9.[27] The sponsor has released data from a phase 3 clinical trial with TRD wherein esketamine, in addition to a newly initiated oral antidepressant, had marginally significant (one-sided $p = 0.010$) improvements as measured by change from baseline in the MADRS total score. Furthermore, clinical response, wherein response was considered a ≥50% improvement in MADRS from baseline, was observed 24 hours post-dose and maintained through day 28 for participants receiving an esketamine and an oral antidepressant combination. The most common treatment emergent adverse events were metallic taste and headache, and other treatment emergent adverse events included nausea, vertigo,

dizziness, and headache.[32] In a clinical trial specifically evaluating the safety of esketamine, the most common treatment emergent adverse events were dizziness (75%) headache (36%), and dissociative symptoms (21%), wherein dizziness and nausea may be dose-related. Dissociative symptoms, as measured by the Clinician Administered Dissociative States Scale (CADSS), were apparent following intranasal dosing and reached their maximum at 30–40 minutes post-dose; however, they were resolved 2 hours post-dose. Notably, dissociative symptoms decrease with repeated dosing. Furthermore, hypertension was observed immediately following esketamine treatment. While symptoms typically resolved 2 hours post-treatment, they may persist post-treatment.[37] Recognizing the potential for adverse events, the FDA has approved a Risk Evaluation and Mitigation Strategy (REMS) to ensure proper usage of esketamine and mitigate the risks of esketamine-related adverse events. Strategies are in place at various levels including the healthcare setting, pharmacies, wholesalers, and patients. Overall, the REMS ensure that esketamine is dispensed only in a medically supervised, certified, healthcare setting. Further, patients are made aware of the possible serious adverse events, and there is continued monitoring of patients to both characterize the risks and support safe usage.[38]

Rapastinel. Rapastinel is an NMDA modulator, behaving similarly to partial agonists of the glycine site. Rapastinel was granted fast track and breakthrough therapy designation by the FDA for adjunctive treatment of MDD.[39] Rapastinel is administered with weekly intravenous doses of 1–10 mg/kg. There was a large placebo effect observed in a phase 2 clinical trial with rapastinel and placebo. Regardless, a rapid reduction in Hamilton Depression Rating Scale scores (HAMD-17) and Bech-6 (a six-item subscale from the HAMD-17) scores were also demonstrated; however, where rapastinel differed, the differences were marginally different from placebo ($p < 0.05$).[40] Seventy percent of participants showed a clinical response wherein a response was defined as 50% improvement from baseline in HAMD-17. Notably, higher doses such as 30 mg/kg demonstrated no antidepressant effects. Of clinical relevance, rapastinel demonstrated changes in Bech-6 scores within 24 hours of infusion, and no psychotomimetic effects were observed.[33] Preclinical trials suggest that rapastinel may have procognitive effects and there are ongoing clinical trials to evaluate this possibility in humans.[41]

AXS-05

AXS-05 is a combinatory pharmaceutical that is a combination of bupropion and dextromethorphan. AXS-05 has been granted fast-track status by the FDA for TRD and breakthrough therapy designation.[42] Dextromethorphan acts as a low-affinity NMDA receptor antagonist, a sigma-1 agonist, and inhibitor of the norepinephrine and serotonin systems with notably limited bioavailability.[43] Bupropion is a norepinephrine and dopamine reuptake inhibitor and acts to increase the bioavailability of dextromethorphan. Available Phase II results from the sponsor indicated that AXS-05 met its primary endpoint in those with MDD. Specifically, there was a highly significant ($p < 0.001$) reduction in MADRS scores over 6 weeks compared to bupropion, and 47% of those who received AXS-05 achieved remission in comparison to 16% of those who received bupropion. Furthermore, the most commonly reported adverse events were nausea, dizziness, dry mouth, decreased appetite, and anxiety.[44]

Other potential future therapeutics

Throughout the year 2018, various glutamate-based therapeutics were granted fast-track status by the FDA. Notably, AV-101, a selective agonist of the NMDA receptor glycine binding site B, was given the fast-track designation for adjunctive treatment of MDD. AV-101 is expected to be administered orally and presents a novel mechanism of action. The sponsor suggested AV-101 has the potential to produce rapid therapeutic effects, similar to those of ketamine.[45] Preclinical studies with AV-101 demonstrated rapid and persistent antidepressant effects in rodent models of depression and did not produce psychotomimetic effects.[46]

Another pharmaceutical agent in the pipeline is AGN-241751, an NMDA receptor modulator with oral administration. It was granted fast-track designation by the FDA for the treatment of MDD, and a phase 2 clinical trial is ongoing.[47]

Gamma-Aminobutyric Acid (GABA)

GABA is the primary inhibitory neurotransmitter in the brain. The GABAergic system interacts with various systems implicated in the pathophysiology of MDD such as the serotonergic system, noradrenergic system, and the hypothalamic-pituitary-adrenal (HPA) axis.[48-50] The impact of the GABAergic system on MDD has been observed in preclinical and clinical models. For example, alterations of metabotropic type B GABA(GABA$_B$) receptors in rodents result in anxiety and depression-like behavior.[51] GABA dysregulation is also observed in humans wherein decreased concentrations of GABA have been reported in those with MDD, and GABA concentrations have been shown to increase following treatment.[52,53] These trends suggest that treatment for MDD normalizes GABA concentrations in the brain. Some treatment regimens employ GABA modulators such as benzodiazepines that modulate the ionotropic type A GABA (GABA$_A$) receptor complex and are often administered alongside traditional antidepressants when

patients exhibit anxiety or insomnia.[54] The GABA$_A$ receptor is the most abundant inhibitory neurotransmitter receptor in the brain and, while altered function of this receptor has been associated with both anxiety and MDD, benzodiazepines have not shown sufficient therapeutic potential as monotherapy for MDD.[55,56] Regardless, targeting the GABA$_A$ receptor provides a potential novel mechanism of treatment for MDD in combination with traditional antidepressants.

Novel therapeutics

Brexanolone (SAGE-547)

Brexanolone is a positive allosteric modulator of the type GABA$_A$ receptor with parenteral administration. Following the filing of a new drug application wherein priority review status was granted, the FDA advisory committee voted in favor of the benefit-risk profile of brexanolone for treatment of postpartum depression.[57,58] Of clinical relevance, if approved, brexanolone would be the first pharmaceutical indicated specifically for postpartum depression. Efficacy of brexanolone has been observed in clinical trials wherein women with postpartum depression received a single intravenous injection of 90, 60 µg/kg per hour, or placebo. Brexanolone, in comparison to placebo, produced a rapid antidepressant response that was marginally significant ($p < 0.05$) within 60 hours post infusion, where response was defined as a 50% reduction in HAM-D total score. Furthermore, response was sustained for up to 30 days. Brexanolone was generally well tolerated, with the most common treatment emergent adverse events being headaches, dizziness, and somnolence. Few treatment-related serious adverse events were observed, notably, the altered state of consciousness and syncope in one participant, and excessive sedation that was resolved following infusion cessation in five participants. No clinically significant changes in laboratory parameters were observed.[59]

SAGE-217

SAGE-217 is a positive allosteric modulator of the synaptic and extrasynaptic GABA$_A$ receptors.[60] SAGE-217 was granted breakthrough therapy designation by the FDA for the treatment of MDD.[61] Preclinical studies have demonstrated an improved drug metabolism and pharmacokinetics profile in comparison to brexanolone. Specifically, SAGE-217 offers low clearance, resulting in higher oral bioavailability and allowing for an oral route of administration.[60] The sponsor has provided results from an open-label phase 2 clinical trial wherein participants with MDD received a daily oral dose of 30 mg. Improvements in depressive symptoms were observed 1 day post-treatment and persisted for 2 weeks following cessation of treatment wherein the differences observed between the treatment and placebo group were highly significant ($p < 0.0001$).[62] Furthermore, a double-blind, randomized, and controlled phase 2 clinical trial wherein the participants also received a daily oral dose of 30 mg demonstrated that there was a mildly significant difference in HAM-D score observed on day 2 and maintained through day 28 ($p = 0.0223$).[63] SAGE-217 appeared to be well tolerated, though minor treatment-related adverse events were observed including sedation, headache, and dizziness.[62]

Immune-Inflammation

The macrophage theory of depression associates cytokines (e.g., macrophage monokines, interferon alpha, and tumor necrosis factor) with depressive symptomatology.[64] The macrophage theory of depression is supported by the observation of increased concentrations of pro-inflammatory cytokines among those with MDD.[65] The increase in cytokines may be indicative of particularly serious profiles of MDD, such as TRD or severe suicidal ideation. A recent study suggests that higher levels of inflammatory proteins are predictive of the severity of TRD.[66] Furthermore, another study demonstrated that there are significantly higher levels of inflammatory markers in patients with MDD who have high suicidal ideation.[67] In addition to their involvement with mood symptomatology, cytokines are involved in cognitive functions such as attention, executive function, learning, and memory, which may contribute to the cognitive impairment observed in MDD.[68,69] The proposed mechanism by which cytokines affect the nervous system is complex; in summary, they can evoke an excitotoxic effect by way of interactions between the monoamine, glutamate, and BDNF systems.[70] Given their involvement in neurotransmitter systems and associated symptomatologic presentation, reduction of inflammatory cytokines presents a novel therapeutic pathway.

Minocycline

Minocycline is a tetracycline antibiotic approved by the FDA for use with various bacterial infections.[71] Minocycline has anti-inflammatory properties and has been used for treatment of rheumatoid arthritis, a chronic inflammatory disease.[72] Several clinical trials are underway exploring the efficacy of minocycline off-label for the treatment of MDD. Recently, results from published clinical trials have been summarized meta-analytically.[73] The dose used throughout various trials ranged from 100 to 300 mg/day. Pooled analyses revealed a significant large antidepressant effect ($p = 0.005$) with the use of minocycline in comparison to placebo. Furthermore, a favorable tolerability profile was observed such that there was no significant difference for study discontinuation between treatment and placebo groups. Notably, minocycline has demonstrated efficacy in treating the cognitive

dysfunction observed with schizophrenia, particularly in the executive functioning domain.[74] While this has yet to be evaluated in those with MDD, similar results could be expected as cognitive dysfunction has been associated with increased levels of C-reactive protein (i.e. a marker of inflammation) in MDD.[75] At the time of this writing, there were several ongoing studies evaluating the efficacy of minocycline as augmentative therapy in MDD and in other mood disorders.

Opioidergic Systems

The opioid system is composed of three types of receptors (i.e. delta, kappa, and mu) which are expressed widely throughout the nervous system. While the opioid system has been commonly implicated in reward processing, pain, and addiction, alterations within the opioid system have also been associated with MDD.[76-79] In addition, anhedonia, a core feature of MDD, has been observed with opioid use, suggesting that the opioid system may be involved in MDD pathophysiology.[80] Various FDA-approved antidepressants, such as venlafaxine and mirtazapine, interact with the opioid system, though they are an SNRI and tetracyclic antidepressant, respectively.[81] Furthermore, preliminary evidence suggests that opioid agonist therapy has efficacy in treating mood disorders.[82] While a concern in the use of opioidergic treatment is the potential for abuse, agents such as naloxone or samidorphan can be used in conjunction with the opioid to mitigate such use.[83,84] The kappa-opioid receptor has demonstrated improvements in mood symptomatology and is of interest in novel therapeutic pathways for MDD.[85]

Buprenorphine+samidorphan

Buprenorphine + samidorphan is a combinatory drug functioning primarily as a kappa-opioid antagonist and a paired mu-opioid agonist and antagonist to offer controlled opioid modulation. Buprenorphine + samidorphan was given fast-track status by the FDA for the adjunctive treatment of MDD; however, the FDA committee recently (November 2018) voted against the approval of buprenorphine + samidorphan. The official decision from the FDA (February 2019) states that it was unable to approve buprenorphine + samidorphan in its current state and requests additional substantial evidence of its effectiveness.[86,87] Ongoing trials are, however, being conducted by the sponsor, and these results are pending. Clinical trials of buprenorphine + samidorphan have used doses from 0.5 mg/0.5 mg to 8 mg/8 mg, and a 1:1 dose has demonstrated the most efficacy and tolerability.[88,89] Buprenorphine undergoes hepatic metabolism wherein it is primarily processed by cytochrome P450 3A4 and, to a lesser extent, CYP 2C8.[90] Clinical trials have demonstrated mixed results for the efficacy of buprenorphine + samidorphan. A phase III trial did not meet its primary endpoint such that changes in MADRS from baseline to endpoint were not significant. However, there may have been a limitation regarding placebo responders, which was addressed in later trials.[91] A phase III trial termed FORWARD-5 has achieved the primary endpoint such that buprenorphine + samidorphan 2 mg/2 mg produced a greater change in MADRS-6 and MADRS-10 in comparison to placebo with marginal significance ($p = 0.026$). Furthermore, a pooled analysis of safety results demonstrated that there were low incidences of serious adverse events and the majority of adverse events that occurred were mild or moderate, consisting of nausea, constipation, dizziness, and sedation. There were no clinically significant changes observed in vital signs, body weight, or echocardiogram parameters. Of particular relevance, there were no reported adverse events associated with abuse or dependence, and there were no reports of opioid withdrawal.[92]

Conclusion

Although success has been found with traditional monoamine antidepressants, there remains a pronounced occurrence of TRD and a prolonged time to response. It is evident by the therapeutics in the pipeline for use with MDD that novel mechanisms of action outside the traditional serotonergic, noradrenergic, and dopaminergic pathways may be beneficial for treatment of MDD. Indeed, novel mechanisms of action allow for a wider selection of treatment options with various therapeutic targets, which may be of great benefit to those with MDD, considering the heterogeneity of the disorder. In particular, fast-acting therapeutics such as ketamine and rapastinel, and therapeutics that have an opportunity to uniquely target systems implicated in the pathophysiology of MDD such as buprenorphine + samidorphan, have the potential to produce cascading benefits throughout patient lives by both improving mood symptomatology and decreasing societal costs by decreased workplace absenteeism and presenteeism.[93] While these novel therapeutics have shown some promising results, additional long-term clinical trials are warranted to determine both the long-term efficacy and monitor for treatment-related adverse events. Though many of the aforementioned therapeutics have rapid results and have shown efficacy in those with TRD, only with long-term clinical trials are we able to determine if these response rates will persist.

Disclosures

During the past 2 years, Dr. Roger S. McIntyre received consultation/speaker fees from the following pharmaceutical companies: Shire, Purdue, Otsuka, Janssen, Lundbeck, Pfizer, Neurocrine, Sunovion, Takeda, Allergan, and Minerva. Dr. Roger S. McIntyre also received research grants from Stanley Medical

Research Institute and CIHR/GACD/Chinese National Natural Research Foundation. No other authors have disclosures to report.

Optional Posttest and CME Certificate

CME Credit Expires: July 31, 2022

Posttest Study Guide

The posttest can only be submitted online. The below posttest questions have been provided solely as a study tool to prepare for your online submission. **Faxed/mailed copies of the posttest cannot be processed** and will be returned to the sender. If you do not have access to a computer, contact NEI customer service at 888-535-5600.

1. Amelia is a 24-year-old patient with treatment resistant depression currently enrolled in a clinical trial involving esketamine. Esketamine is an antagonist at which of the following receptors?
   A. AMPA
   B. NMDA
   C. mGluR

2. Marsha is a 31-year-old patient with postpartum depression who is intrested in enrolling in a clinical trial testing the novel antidepressant brexanolone. Brexanolone is hypothesized to work due to its actions with which of the following neurotransmitter systems?
   A. GABA
   B. Glutamate
   C. Opioid

3. Clark is a 43-year-old patient with treatment resistant depression currently enrolled in a clinical trial testing the novel antidepressant SAGE-217. Compared to brexanolone, SAGE-217 differs in that it:
   A. Is a positive allostric modulator of GABA-B receptors
   B. Requires intravenous administration
   C. Has higher oral availability

4. Patrick is a 34-year-old patient with MDD. Lab results indicate that this patient has increased levels of pro-inflammatory cytokines. Which of the following agents is hypothesized to ameliorate symptoms of depression primarily via its anti-inflammatory properties?
   A. SAGE-217
   B. Minocycline
   C. Rapastinel
   D. Buprenorphine/samidorphin combination

Optional Online Posttest and CME Certificate Instructions

1. Read the article
2. Complete the posttest and evaluation, available only online at www.neiglobal.com/CME (under "CNS Spectrums")
3. Print your certificate (passing score = 70% or higher)
